1

Method and device for measuring, determining and controlling flatness of a metal strip

5 Technical Field of the Invention

The invention relates to a method and a device for measuring, determining and controlling flatness of a substantially long and flat sheet or strip of material, such as copper, steel,
10 aluminium or other materials such as plastics, in a continuous or semi-continuous production process.

More particularly it is a method and device for measuring, determining and controlling flatness in a cold or hot rolling
15 mill.

The invention further deals with a method and device for measuring, determining and controlling flatness using human-machine interfaces and control algorithms.
20

Background of the invention

In the rolling of strip and sheet materials it is common
25 practice to roll a material to desired dimensions in a cold or hot rolling mill stand and then feed the resulting strip to a coiler where it is wound up into a coil. In figure 1 is a flatness control is illustrated that typically comprises of three main parts, measurement, control and actuators (that
30 correct the flatness error). The difficulty with the flatness control consists on achieving a very good flatness. The reason

98/087 - 031231/UR

2

why the flatness is not always ~~is~~ perfect, is that all three parts have a number of limitations.

The measurement is for example often discrete both across the width of the strip, as it has a limited number of measurement zones, and along the strip, as there are only a limited number of ~~four~~ measurements done per rotation (say, four measuring zones in the rotational direction). The control has a complex mathematics that cannot always be performed in real time and the actuators are only corecting certain type of errors and it is not sure they can correct any shape of flatness error. For example, a bending and a tilting actuator can correct only a shape that is a sum of a parable and a straight line, but of course the flatness error can in principle have any irregular shape.

A metal strip that is subject to different degrees of reduction across its width will be elongated in varying length over different sections of the strip. Normally, the reduction results in certain pre-defined stress profiles for the strip.

The difference between the measured strip flatness and a target flatness curve is defined as the "flatness error". Practically the flatness error of the strip can be gauged by a special measuring roll, e.g. a Stressometer roll, an ABB product.

Prior Art

Several different methods have been developed to correct the flatness error by a so-called flatness control operation. All

SE7363 - G31731/UR

3

of these methods are based upon local modifications of the gap between rolls.

5 The tension in the strip between a mill stand and a coiler is carefully monitored and it is known to measure tension distribution across a strip in order to regulate the flatness of the rolled material.

10 In US 3,481,194 Sivilotti and Carlsson disclose a strip flatness sensor. It comprises a measuring roll over which the strip passes between a mill stand and, for this example, a coiler. The measuring roll detects the pressure in a strip at several points across the width of the strip. The pressure represents a measure of the tension in the strip. The measurements of
15 tension in the strip result in a map of flatness in each of several zones across the width of the strip.

US 4,400,957 discloses a strip or sheet mill in which tensile stress distribution is measured to characterise flatness. The
20 measures of flatness are compared to a target flatness and a difference between measured flatness and target flatness is calculated, as a flatness error. The flatness error is fed back to a control unit of the mill stand, so as to regulate and control flatness in the strip in order to approach a zero
25 flatness error.

Discrete flatness sensors and rolling mills with several actuators have drawbacks in that the sensors are not measuring continuously. This means that certain types of flatness errors
30 are not detected. In addition to this, due to physical limitations, actuators cannot correct any type of flatness error, even if these are detected.

SE:PDF 331231/UR

One further disadvantage is increased complexity in sensor processing, actuator response prediction and the need of precise mathematical mappings between these sensors and
5 actuators.

Normally the optimization of the flatness is done by different compensations of the space mapping function. These involve a great deal of numerical and process control methods. Typical
10 examples are artificial neural networks, multivariable control, adaptive control, etc. These are difficult for plant operators to understand and handle.

Moreover, though additional information may be available for
15 the operator from e.g. visual inspection of the strip, the operator cannot easily translate this information into the existing mathematical formalism of the flatness control. For example, the operator may see certain patterns on the strip like "quarter-buckles", but it is not obvious how he may use
20 this information to amend the flatness control paradigm.

In the following the background of control algorithms for control equipments will be described for the purpose of later understanding of the invention. In doing this, ~~referens~~
25 references will be made to the following parameters:

N = Number of measurement zones (number of samples for actuator function)
P = Number of actuators
30 b_i = Flatness error for zone i ($i=1,...,N$) it is the flatness error space

ABB - 031231/UP

5

$a_{i,j}$ = Actuator function at measurement zone i for actuator j ,
($i=1,\dots,N$; $j=1,\dots,P$)

A = The mill matrix, with components $a_{i,j}$ used for space mapping

x_j = actuator parameter to calculate, normalized in range

5 [0,...,1], it is the actuator space

A^T = Means the transpose of a matrix A

R^n = It is the space of real n -dimension vectors $\{x_1, x_2, \dots, x_n\}$.

The term space denotes a vector space. We use the vector space
10 of matrices of different sizes and the vector space of
polynomials.

The mill matrix A is obtained from the mill manufacturer, from
measurements or identification operations, and the flatness
15 error matrix b is measured on-line with the measurement roll.
These matrices are related to the actuator parameter matrix x
by the following formula:

$$Ax=b \quad (1)$$

20

Flatness control means generally finding the vector x when the
vector A is a given constant and b is measured on-line.

Since A is not a square matrix (in general $N \geq P$), there are
more equations N than unknowns P for the system of equations
25 represented by (1). That means, in general, there is no a
unique solution but there can be found an x such that b is
"close" to Ax . Here "close" is in terms of a Euclidian distance
expressed as a norm in the R^N space.

30 If x varies and if the columns of A are linearly independent,
then the product Ax describes a space on R^N called "the column
space of A " or "the range of A " - notation $R(A)$, or "the span

FIGURE 2 - FIGURE 2

6

of the columns of A'' . It is known from elementary geometry in 2D/3D spaces and from functional analysis in N-space that the closest distance is given by an orthogonal projection: the smallest distance between b and Ax is the projection of b on the space of Ax , see figure 2.

Two arbitrary vectors v and w are orthogonal when their inner product denoted $\langle v, w \rangle$ is zero. For a matrix vector space, the inner product is defined as the product $v^T w$, so orthogonality means $v^T w = 0$. For our case, let $r = b - Ax$ be the residual (the error between a solution Ax and the vector b). The smallest residual is the orthogonal projection of r onto Ax , which according to the definition is:

$$0 = A^T r = A^T (b - Ax) \quad (2)$$

By separating the terms, we obtain:

$$A^T A x = A^T b \quad (3)$$

This is called in literature the *normal equation*. The factor $A^T A \in \mathbb{R}^{N \times N}$ is called the Gram matrix of A (is always a symmetric square matrix). Multiplying (2) with $(A^T A)^{-1}$ we obtain x :

$$x = (A^T A)^{-1} A^T b = A^{PL} b \quad (4)$$

The term $A^{PL} = (A^T A)^{-1} A^T$ is called the *left pseudo-inverse matrix* of A .

The formula (4) above is used for the "model-based method" in the existing Stressometer 5.0/6.0 flatness control equipment

957481 - 181381/UR

7

and also by a majority of other producers of flatness control equipment. Other descriptions of this method appear under the names such as "least square method", "orthogonal vectors" or "residual square minimization", however, all of these are less
5 general formulations of the vector space and orthogonal projection described above. For example orthogonal vectors may be obtained by a Gram-Schmidt orthogonalization procedure; however the orthogonalization is just another way of computing the pseudo-inverse.

10

Image morphing (short for image metamorphosis) is a popular technique for creating a smooth transition between two 2D images. Morph is the process of changing one object to another one.

15

In Amorphium, for example, one can morph organic shape 1% to 100%. Morphing organic shapes or shapes with the same number of polygons and vertices is called basic morph. All of Amorphium basic object (organic) have the same number of polygons and
20 vertices and therefor can be morphed 100%.

Morphing synthetic or shapes with different number polygons and vertices is called shape morph. With shape morph Amorphium attempts to build a map between the vertices of one object and
25 the vertices of the other. Therefor you do not end up with the morph shape looking identical to the one you morph it with. All the standard shapes are synthetic, so are imported shapes FontMan, Meshman and shapes that have been merged. But if you morph an object that is synthetic, with an altered duplicate o
30 it, it will morph 100% because it is considered basic morph. I has the same number of polygons and vertices.

507193 - 181231/UR

8

The method can be applied to volume-based representations of objects and the result is a smooth transition between two 3D objects (3D metamorphosis or 3D morphing). There are several different algorithms to create the transition depending on the intended function.

Summary of the invention

As strip products with a high degree of flatness are essential for the competitiveness of mills today, the object of the present invention is to solve above indicated problems and present a new method and a device for measuring, determining and controlling flatness of a substantially long and flat sheet or strip of material.

Flatness Control, FC, essentially maps points moving in the multidimensional space of the measured flatness error into points determined in the multidimensional space of the actuators such that certain optimality conditions are met. This is the traditional mapping used today in FC, we call this as the 'first mapping'.

The first mapping is often difficult to optimize due to the nature of the actuator space and due to the sensor data vs. reference values used for the computation of the flatness error. For instance the complete action of all the actuators is not linear in the individual actuators, it cannot produce the optimal mapping or the mapping (possible combinations of actuator positions) is not unique.

PCT/SE/03/001001

Another factor that limits the control is the discrete nature of the measurement. A discretization is inherent with most of the current measurement technologies both across the strip width (the measurement zones of the measuring roll) and along the strip length (sensors measuring when in contact with the strip).

The present invention proposes a solution to the problems discussed above by introducing a second mapping. This second mapping can be made from reference models such as video samples or mathematical functions to output space optimization matrices. The reference models enter into the computation of the main mapping. The result is increased accuracy and locality of the flatness control. A further advantage is a vast increase in sampling granularity that translates into more accurate and timely flatness control.

The method of the invention is achieved by,

- that a second mapping is made to optimization algorithms acting in actuator model and sensor spaces using visual or image information, and
- that the measured flatness vector is enhanced with information from a virtual strip.

The present invention apply to any type of flatness measurement that is discrete.

The present invention creates a mathematical map between the sensor space and the actuator space that improve substantially the deficiencies with known controlling methods. This comes from that extra information is entered into the system from the user, or from a visual sensor, about the nature of the flatness

467287 - 131231/0R

10

error and that this information is used in a better way to optimize the actuator behavior, for any type of known controller. Accordingly, a visual equipment and visual operation, on sensor data, such as sensor fusion or morphing is
5 used in the method according to the invention, as well as a control architecture that implements a space mapping.

A method according to the present invention will increase the control speed substantially as the response time decreases.

10

Brief Description of Drawings

For better understanding of the present invention, reference
15 will be made to the below drawings/figures.

Figure 1 illustrates a known flatness control equipment.
Figure 2 illustrates a simple orthogonal projection.
Figure 3 illustrates a control system according to the
20 invention.

Figure 4 illustrates a mathematical model generated strip.
Figure 5 illustrates a number of examples of flatness profiles
Figure 6 illustrates the fine-tuning of the reference model or the synchronization of the sampling.
25 **Figure 7** illustrates an example of a continuous strip prediction.

Detailed Description of Preferred Embodiments

30

Flatness control, as used in metal rolling mill industry is, from a mathematical perspective, a mapping of an abstract spac

947782 13 FEB 04

11

- of sensor-originated vectors into a space of actuators. When fine-tuning the control to specific mill conditions, one uses traditional paradigms corresponding to the implemented mathematical level of the control, such as "transfer function",
- 5 "poles and zeroes in the state space", "dynamic behavior", "least-squares" and different parameterization or penalty functions. With the advent of the IT and virtual reality architectures, it is increasingly the case that virtual strip models are available from video captures or mathematical
- 10 models. Thus the idea is to move the tuning operation from the control abstract level up to the real physical properties that can be seen by an operator when using different visualization and virtual reality techniques.
- 15 The present invention presents a method to use the information contained in the virtual strip models to improve the flatness control algorithm. The main features of the invention are:
- The measured flatness vector is enhanced with information
 - 20 from the virtual strip using a morphing technique (enhancement of the first space mapping).
 - By this operation the sampling granularity increases. That result in better and more accurate flatness control.
 - Since sampled data is available in shorter time interval, th
 - 25 control speed increases (response time decreases) substantially.
 - The virtual strip is mapped to a vector space optimization algorithm. This in effect is a second vector mapping that performs a fine, local adjustment of the control optimizatio
 - 30 (creation of a second space mapping).

757281 - 031231/UP

12

In short, the invention states that increased flatness control precision can be achieved by a two-way space mapping in which visual or other continuous or near continuous a-priori strip information enhances (a) the measurement (b vector) and a
5 traditional control loop and (b) the optimization algorithms that tells how x is computed such that to minimize the residual $|Ax - b|$.

10 In figure 3 is illustrated a control system according to the invention, where:

- A is a measurement roll, that produces a vector of flatness values per each measurement zone.
- B is a Morphing unit (software in existing equipment or dedicated device), that is a part of the HMI-software.
- 15 • C denotes reference strip models used for morphing. These are picture files generated from video or using laser captures or results from mathematical modelling.
- D are target stress profiles (reference). For the purpose of the method, the granularity of the target stress profile is
20 the same as the granularity of the reference strip models.
- E is flatness control computer ~~using e.g.~~ executing the algorithm described above.
- F ~~is~~ are space conversion matrices that describe mathematically the local properties of the strip (edge,
25 middle etc). Each matrix is mapped to a reference strip model.
- G is a mill model, that is part of the existing flatness control, and it is a matrix ("the Mill Matrix").
- H ~~is~~ are actuators that correct flatness.

30

The mill operator has extra information about the nature of th

577032 - 031231-UP

13

inspection. By contrast, the measured value contains only a truncated part of all this information due to the discrete sampling. A video frame can contain information at sub-millimeter granularity while the flatness measurement may have only granularity between 10 cm and up to 0.25 m. For example a video camera (or visual inspection) can show clearly so-called "quarter buckles" but when sampling with a measurement roll, these buckles are not completely detectable. This is illustrated in Figure 6: on a strip picture generated from a video capture, discrete roll measurement samples may fall anywhere inside or outside buckles such that the buckles cannot be deduced from roll measurements alone. The visual information can be generated also from mathematical models (so called grey, white or black models), an example of a mathematically generated model strip is illustrated in figure 4. According to the invention all types of generated or photo/video captured images can be used.

According to the present invention, this information is added to the measured information from the reference model in order to improve the space mapping optimization. The information is typically morphed.

The operator has a number of reference models that have as output stress profiles, see figure 5, that can be morphed with the real measurement data. These models are obtained for example from digital translations of video captures.

To accomplish the morphing the selected reference model need to be scaled and synchronized to match the measured data.

9576.88 - 131231.00

14

One alternative to do this is to make a visual mark on the strip (from video capture) where the measurement was done. This can be done for example by using a laser ray.

- 5 In the graphical user interface the operator (or a pattern matching algorithm) can fine-tune the reference model horizontally to match the measured data. This method is shown in figure 7.
- 10 The morphing algorithm modifies the reference model according to the measurement data resulting in a data set that is closer to the reality.

The morphing function can be calculated in different ways but
15 essentially every measured data point affects several reference model points gradually.

This new data set can be used to calculate a flatness error that is more accurate as compared to the existing system.

- 20 The target profile is subtracted from the morphed profile (a vector subtraction) in order to compute a flatness error. This operation can be performed if the granularity of the target and the morphed signal is the same. High granularity target profiles can be obtained by simply filling in repetitively the
25 same profile until the required granularity is achieved, or by using pictures or video captures from a de post-facto strip processing as described in the Patent EP 1 110 635 A1 Method and device for controlling flatness (Jonsson, Meyer, 1999). The resulting flatness error has a much higher granularity than
30 what is traditionally obtained from the original measured samples. This has the effect that the flatness control will be more accurate, faster and has a better prediction capacity.

45/1581 031211/UR

15

The mill operator has extra information about the nature of the flatness fault, e.g. from a video camera or visual inspection. By contrast, the measured value does not contain all this
5 information due to sampling. For example a video camera (or visual inspection) can show so-called "quarter buckles" but when sampling with a measurement roll, these buckles are not completely detectable.

10 The operator has a number k of reference models of pre-defined stress profiles. These models are obtained from for example digital translations of video captures.

Information about the nature of the flatness fault can be used
15 to design the flatness control algorithm to concentrate on compensating zones where the problem is most significant. If for example the strip has the pattern "wave edges" the actuators need to compensate strip edges rather than the center.

20

The present invention propose that there is established a one-to-one mapping: each reference model of the pre-defined stress
profiles has associated a matrix that describe the weight of each measurement zone for the flatness error correction. These
25 weight matrices are used in the flatness control algorithm.

The operator, or a pattern matching software, decides witch reference model is best to use. The reference model is mapped to one of the weight matrices. This mapping is the second
30 vector space mapping, and it is a key element of this invention.

SECRET TELETYPE

16

There are some patents from e.g. Hitachi/Siemens, that use certain pattern matching techniques. However, these patents are focused on the use of certain algorithms (fuzzy, neuronal nets) for enhancing measurement and are not referring to the control algorithm as this invention does. In other words, these patents claim improvements in what we call the first space mapping. By contrast, the present invention claims that substantially increased flatness control accuracy can be achieved by the dual space mapping.

10

Mathematically, that means each reference model M_i (where i is the index of the model), is mapped to a unique matrix K_i . The matrix K_i is a square matrix of size $N \times N$ (N being the number of measurement zones). The matrix has zero in all positions except the main diagonal, where there is the weight desired for the action of actuators on the particular zone of size.

The near-continuous space obtained after morphing, gives, after a measurement sampling, a degree of prediction since the continuous subspace between two samples is now available. The prediction horizon is equal to at least the size of the reference strip model. That means the control algorithm can be improved in this strip region, by performing an autoregressive control scheme. The operator has the visualization and command possibilities as shown schematically in figure 6.

The strip is generated on the operator station using computer graphics tools (shadowing, material texture, translations etc). The strip is shown moving, in the same fashion as a video would show (so called virtual reality). The input to this function is the measured data from the measuring roll and the morphed surface. The measuring sensors touch the strip e.g. in the posi-

557032 - 031531/UK

17

tions denoted as A, B, C, D in figure 7. The reference model used for morphing has a length 1. Figure 7 shows the case when the prediction horizon is 1. This length covers 3 measurement samples A, B and C. The colors within the prediction area are mapping the difference between the actual measurement and the predictive values, in the usual way done with loggers, Matlab programs etc. For example red color means large error, yellow means medium, green is low error and the colors have gradients in between. The mill operator, by modifying the prediction horizon in the range [0, 1], and the morphed reference model, can verify which case is best suited for rolling.

To summarize, the invention involves the following;

- a second mapping - from reference models to output space
- 15 optimisation matrices - virtual strip is directly mapped to a vector space optimisation algorithm,
- reference models enter into the computation of the main mapping - the measured flatness vector is enhanced with information from the virtual strip using a morphing technique,
- 20 - use of reference pictures/models/descriptions of the strip to enhance flatness error - morphing technique,
- use of reference pictures/models/descriptions of the strip with an associated weight matrix to concentrate on compensating zones where the problem is most significant,
- 25 - space change.

The method according to the invention may, at least partly, be performed under control of a set of computer readable instructions or code means contained in a computer program storage device for making a computer or processor perform any of the steps of the abovedescribed method.

951120 02531/UR

18

The invention may also use a computer readable product for carrying out the method according to the invention.

- 5 While the present invention has been described in terms of the preferred embodiments, the invention is not limited thereto, but can be embodied in various ways without departing from the principle of the invention as defined in the claims.

Claims

1. Method for optimizing the measuring and determining of flatness faults of a strip of rolled material where a first mapping is made of the strip in at least one zone after passing through a mill stand,
5 **characterized by,**
- that a second mapping is made to optimization algorithms acting in actuator model and sensor spaces using visual or image information, and
10 - that the measured flatness vector is enhanced with information from a virtual strip.
2. Method according to claim 1,
15 **characterized by,**
that the virtual strip is mapped to a vector space optimization algorithm.
3. Method according to claim 1 or 2,
20 **characterized by,**
that a morphing technique is used.
4. Method according to any of the preceeding claims,
characterized by,
25 the result of the mapping is added by morphing to the measured information from a reference model.
5. Device for optimizing the measuring and determining of flatness faults of a strip of rolled material after passing through a mill stand,
30 **characterized by,**

SE/OSF 131231/UR

20

that means for synchronizing measured data with video samples and with the currently perform optimization algorithm is arranged.

- 5 6. A computer program comprising computer program code means
for carrying out the steps of a method according to claim 1-4.
7. A computer readable medium comprising at least part of a
computer program according to claim 6.
- 10 8. A computer program, according to claim 6, that is, at least
partially, provided through a network, such as e.g. internet.

31/03/04 - 131231/UP

21

Abstract

The invention refers to a method for optimizing the measuring and determining of flatness faults of a strip of rolled material where a first mapping is made of the strip in at least one zone after passing through a mill stand.

The invention is achieved by,

- that a second mapping is made to optimization algorithms acting in actuator model and sensor spaces using visual or image information, and
- that the measured flatness vector is enhanced with information from a virtual strip.
